# Outline

## Quality metrics

- Supervised machine learning problems

## Generalisation

## Estimating quality

- Methodology

## Learning and generalisation

- Introduction

- Bias and variance

- Generalisation

## PAC Learning

- The realisable setting

# Classification

## The classifier as a decision rule

A decision rule  $\pi(a|x)$  generates a **decision**  $a \in [m]$ . It is the conditional probability of  $a$  given  $x$ .

## A note on conditional probabilities

Even though normally conditional probabilities are defined as  $P(A|B) = P(A \cap B)/P(B)$ , the probability of the decision  $a$  is undefined without a given  $x$ . So it's better to think if  $\pi(a|x)$  as a collection of distributions on  $a$ , one for each value of  $x$ .

## Deterministic predictions given a model $P(y|x)$

Here, we pick the most likely class:

$$\pi(a|x_t) = \mathbb{I} \left\{ a = \arg \max_y P(y|x_t) \right\}$$

## Deterministic predictions given a model $P(y|x)$

Here, we randomly select a class according to our model:

$$\pi(a|x_t) = P(y_t = a|x_t)$$

# Accuracy as a classification metric

## The accuracy of a single decision

$$U(a_t, y_t) = \mathbb{I}\{a_t = y_t\} = \begin{cases} 1, & \text{if } a_t = y_t \\ 0, & \text{otherwise} \end{cases}$$

## The accuracy on the training set

$$U(\pi, D) \triangleq \frac{1}{T} \sum_{t=1}^T \sum_{a=1}^m \pi(y_t | x_t)$$

## The expected accuracy of a decision rule

If  $(x, y) \sim P$ , the accuracy  $U$  of a stochastic decision rule  $\pi$  under the distribution  $P$  is the probability it predicts correctly

$$U(\pi, P) \triangleq \int_{\mathcal{X}} dP(x) \sum_{y=1}^m P(y|x) \pi(y|x)$$

# Regression

## The regressor as a decision rule

A decision rule  $\pi$  generates a **decision**  $a \in \mathbb{R}^m$ .

- ▶ For **randomised** rules,  $\pi(a|x)$  is the conditional density of  $a$  given  $x$ .
- ▶ For **deterministic** rules  $\pi(x)$  is the prediction for  $x$ .

## Mean-Squared Error on a Dataset

The mean-square error is simply the squared difference in predicted versus actual values:

$$\frac{1}{T} \sum_{t=1}^T [y_t - \pi(x_t)]^2$$

## Expected MSE

If  $(x, y) \sim P$ , the expected MSE of a deterministic decision rule  $\pi : X \rightarrow \mathbb{R}$  is

$$\int_X \int_Y dP(x, y) [y - \pi(x)]^2.$$

# Training and overfitting

## Training data

- ▶  $D = ((x_t, y_t) : t = 1, \dots, T)$ .
- ▶  $x_t \in X, y_t \in Y$ .

Assumption: The data is generated i.i.d.

- ▶  $(x_t, y_t) \sim P$  for all  $t$  (identical)
- ▶  $D \sim P^T$  (independent)

The optimal decision rule for  $P$

$$\max_{\pi} U(\pi, P) = \max_{\pi} \int_{X \times Y} dP(x, y) \sum_a \pi(a|x) U(a, y)$$

The optimal decision rule for  $D$

$$\max_{\pi} U(\pi, D) = \max_{\pi} \sum_{(x,y) \in D} \sum_a \pi(a|x) U(a, y)$$

# Estimating the quality of a classifier

The measured accuracy  $U(\pi, D)$  is not equal to the actual accuracy  $U(\pi, P)$ .

## A taste of theory

If  $|U(\pi, D) - U(\pi, P)| \leq \epsilon$ , how good is our decision rule?

Removing the absolute value, we get

$$U(\pi, P) - U(\pi, D) \leq \epsilon \quad (1)$$

$$U(\pi, D) \geq U(\pi, P) - \epsilon. \quad (2)$$

So, our decision rule will be at most  $\epsilon$ -worse in practice.

## Learning theory

- ▶ If we choose  $\pi$  to maximise  $U(\pi, D)$ , how does it compare to  $\max_{\pi} U(\pi, P)$ ?
- ▶ How does  $\epsilon$  depend on  $D, P$ ?

# The Train/Validation/Test methodology

## Main idea

Use each piece of data once to make decisions and measure

## Training set

Use to decide low-level model parameters

## Validation set

Use to decide between:

- ▶ different hyperparameters (e.g.  $K$  in nearest neighbours)
- ▶ model (e.g. neural networks versus kNN)

## Test set

Use to measure the final quality of a model

# Cross-validation (XV)

## Idea

- ▶ Use XV to select hyperparameters instead of a single train/valid test.

## Methodology

- ▶ Split training set  $D$  in  $k$  different subsets
- ▶ At iteration  $i$
- ▶ Use the  $i$ -th subset for validation
- ▶ Use all the remaining  $k - 1$  subsets for training
- ▶ Average results on validation sets

# Bootstrapping

## Idea

- ▶ How to take into account variability?
- ▶ Resample the data and repeat your calculations for each resample

## Bootstrap samples

- ▶ Input: Data  $D$ , of size  $T$
- ▶ For  $t$  in  $\{1, \dots, T\}$ 
  - Select  $i$  uniformly in  $[T]$  – Add the  $i$ -th point to  $D_b$
- ▶ Return  $D_b$

# The wrong way to do XV for subset selection

1. Screen the predictors: find a subset of “good” predictors that show fairly strong (univariate) correlation with the class labels.
2. Using just this subset of predictors, build a multivariate classifier.
3. Use cross-validation to estimate the unknown tuning parameters and to estimate the prediction error of the final model.

## Is this a correct application of cross-validation?

Consider a scenario with  $N = 50$  samples in two equal-sized classes, and  $p = 5000$  quantitative predictors (standard Gaussian) that are independent of the class labels. The true (test) error rate of any classifier is 50%.

# The right way to do XV for feature selection

1. Divide the samples into  $K$  cross-validation folds (groups) at random.
2. For each fold  $k = 1, 2, \dots, K$
3. Find a subset of “good” predictors that show fairly strong (univariate) correlation with the class labels, using all of the samples except those in fold  $k$ .
4. Using just this subset of predictors, build a multivariate classifier, using all of the samples except those in fold  $k$ .
5. Use the classifier to predict the class labels for the samples in fold  $k$ .

# Learning and generalisation

How well can decision rule perform?

## Estimation theory view

- ▶ Bias: The expected difference between the estimated value and the unknown parameter
- ▶ Variance: The expected difference between the estimated value and the unknown parameter

## Learning theory view

- ▶ Approximation ability: How well a class of rules can approximate the optimal one.
- ▶ Statistical error: How easy it is to choose the best rule in the class.

# The bias/variance trade-off

- ▶ Dataset  $D \sim P$ .
- ▶ Predictor  $f_D(x)$
- ▶ Target function  $y = f(x) + \epsilon$
- ▶  $\mathbb{E} \epsilon = 0$  zero-mean noise with variance  $\sigma^2 = \mathbb{V}(\epsilon)$

## MSE decomposition

$$\mathbb{E}[(f - f_D)^2] = \mathbb{V}(f_D) + \mathbb{B}(f_D)^2 + \sigma^2$$

## Variance

How sensitive the estimator is to the data

$$\mathbb{V}(f_D) = \mathbb{E}[(f_D - \mathbb{E}(f_D))^2]$$

## Bias

What is the expected deviation from the true function

$$\mathbb{B}(f_D) \triangleq \mathbb{E}[(f_D - f)]$$

## Example: mean estimation

- ▶ Data  $D = y_1, \dots, y_T$  with  $\mathbb{E}[y_t] = \mu$ .
- ▶ Goal: estimate  $\mu$  with some estimator  $f_D$  to minimise
- ▶ MSE:  $\mathbb{E}[(y - f_D)^2]$ , the expected square difference between new samples and our guess.

### Optimal estimate

To minimise the MSE, we use  $f^* = \mu$ . This gives us two ideas:

### Empirical mean estimator:

- ▶  $f_D = \sum_{t=1}^T x_t / T$ .
- ▶  $\mathbb{V}(f_D) = \mathbb{E}[f_D - \mu]^2 = 1/\sqrt{T}$
- ▶  $\mathbb{B}(f_D) = 0$ .

### Laplace mean estimator:

- ▶  $f_D = \sum_{t=1}^T (\lambda + x_t) / T$ .
- ▶  $\mathbb{V}(f_D) = \mathbb{E}[f_D - \mu]^2 = \frac{1}{1+\sqrt{T}}$
- ▶  $\mathbb{B}(f_D) = O(1/T)$ .

# A proof of the bias/variance trade-off

- ▶ RV's  $y_t \sim P$ ,  $\mathbb{E}[y_t] = \mu$ ,  $y_t = \mu + \epsilon_t$ .
- ▶ Estimator  $f_D$ ,  $D = y_1, \dots, y_{t-1}$ .

$$\begin{aligned}\mathbb{E}[(f_D - y_t)^2] &= \mathbb{E}[f_D^2] - 2\mathbb{E}[f_D y_t] + \mathbb{E}[y_t^2] \\&= \mathbb{V}[f_D] + \mathbb{E}[f_D]^2 - 2\mathbb{E}[f_D y_t] + \mathbb{E}[y_t^2] \\&= \mathbb{V}[f_D] + \mathbb{E}[f_D]^2 - 2\mathbb{E}[f_D]\mathbb{E}[y_t] + \mathbb{E}[y_t^2] \\&= \mathbb{V}[f_D] + \mathbb{E}[f_D]^2 - 2\mathbb{E}[f_D]\mu + \mathbb{E}[y_t^2] \\&= \mathbb{V}[f_D] + \mathbb{E}[f_D]^2 - 2\mathbb{E}[f_D]\mu + \mathbb{E}[(\mu + \epsilon_t)^2] \\&= \mathbb{V}[f_D] + \mathbb{E}[f_D]^2 - 2\mathbb{E}[f_D]\mu + \mathbb{E}[\mu^2 + 2\mu\epsilon_t + \epsilon_t^2] \\&= \mathbb{V}[f_D] + \mathbb{E}[f_D]^2 - 2\mathbb{E}[f_D]\mu + \mu^2 + \sigma^2 \\&= \mathbb{V}[f_D] + (\mathbb{E}[f_D] - \mu)^2 + \sigma^2 \\&= \mathbb{V}(f_D) + \mathbb{B}(f_D)^2 + \sigma^2\end{aligned}$$

# Generalisation error

## Regret decomposition

Let the optimal rule be  $\pi^* \in \Pi$ , the best approximate rule be  $\hat{\pi}^* \in \hat{\Pi}$  and our rule be  $\hat{\pi} \in \hat{\Pi}$ . We call the difference between the performance of  $\pi^*$  and  $\hat{\pi}$  our **regret**:

$$\underbrace{U(\pi^*, P) - U(\hat{\pi}, P)}_{\text{regret}} = \underbrace{U(\pi^*, P) - U(\hat{\pi}^*, P)}_{\text{approximation error}} + \underbrace{U(\hat{\pi}^*, P) - U(\hat{\pi}, P)}_{\text{estimation error}}$$

We can bound the regret by bounding each term separately.

- ▶ The **approximation error** tells us how expressive our class of rules is, i.e. how much we lose by looking at a restricted class  $\hat{\Pi}$  of rules. It is similar to estimator **bias**.
- ▶ The **statistical error** tells us how well the empirical performance on  $D$  approximates the true performance. It is similar to estimator **variance**.
- ▶ As a rule of thumb, the larger our class, the better the possible approximation but the higher the statistical error.

# Approximation error

- ▶ Our model limits us to a set of decision rules  $\hat{\Pi} \subset \Pi$ .
- ▶ The most we could do is find the best rule in  $\hat{\Pi}$ .
- ▶ This still leaves a gap:

$$\Delta \triangleq \max_{\pi \in \Pi} U(\pi, P) - \max_{\hat{\pi} \in \hat{\Pi}} U(\hat{\pi}, P)$$

The gap can be characterised in some cases.

Example:  $\epsilon$ -net on Lipschitz  $U(\cdot, P)$ .

- ▶ Assume  $U(\pi, P)$  is a Lipschitz function of  $\pi$  for all  $P$ , i.e.  $|U(\pi, P) - U(\pi', P)| \leq Ld(\pi, \pi')$  for some metric  $d$ .
- ▶ Let  $\hat{\Pi}$  be an  $\epsilon$ -net on  $\Pi$ , i.e.  $\max_{\pi \in \Pi} \min_{\pi' \in \hat{\Pi}} d(\pi, \pi') = \epsilon$ .
- ▶ Then  $\Delta \leq L\epsilon$ .

# Estimation error

- ▶ First, let us bound  $U(\hat{\pi}^*, P) - U(\hat{\pi}, P)$  by making an assumption.
- ▶ Then, we can prove that our assumption holds with high probability.

## Lemma

Let  $f, g : S \rightarrow \mathbb{R}$ . If  $\|f - g\|_{\infty} \leq \epsilon$  and  $f(x) \geq f(z)$ , while  $g(y) \geq g(z)$ , for all  $z$ , i.e.  $x, y$  maximise  $f, g$  respectively

$$f(x) - f(y) \leq 2\epsilon.$$

This holds as:  $f(x) - f(y) \leq g(x) + \epsilon - f(y) \leq g(y) + \epsilon - f(y) \leq 2\epsilon$ .

## Corollary

If  $|U(\pi, P) - U(\pi, D)| \leq \epsilon$  for all  $\pi$  then

$$U(\hat{\pi}^*, P) - U(\hat{\pi}, P) \leq 2\epsilon$$

- ▶ Let us now prove that, with high probability,  
 $|U(\pi, P) - U(\pi, D)| \leq \epsilon$ .

## Bounding the estimation error

For any fixed rule  $\pi \in \Pi$  and utility function  $U : \Pi \times X^T \rightarrow [0, 1]$ ,

$$P^T(|U(\pi, D) - U(\pi, P)| \geq \epsilon) \leq 2 \exp(-2T\epsilon^2).$$

This is a direct application of Hoeffding's inequality<sup>1</sup>. Taking the union bound over the set  $\hat{\Pi}$  gives:

$$P^T(\exists \pi \in \hat{\Pi} : |U(\pi, D) - U(\pi, P)| \geq \epsilon) \leq 2|\hat{\Pi}| \exp(-2T\epsilon^2).$$

Setting the right side equal to  $\delta$  and re-arranging,

$$P^T\left(\max_{\pi \in \hat{\Pi}} |U(\pi, D) - U(\pi, P)| \geq \sqrt{\frac{\ln(2|\hat{\Pi}|/\delta)}{2T}}\right) \leq \delta.$$

**Example:  $\epsilon$ -net.**

In a  $n$  dimensional space we require  $|\hat{\Pi}| = O(\epsilon^{-n})$ . This means that our statistical error is  $O(\sqrt{n \ln(1/\epsilon\delta)/T})$ .

---

<sup>1</sup>See Hoeffding's inequality in the confidence intervals presentation 

# The finite hypothesis algorithm

- ▶ Input: a finite set of rules  $\hat{\Pi}$ , data  $D$ , utility  $U$
- ▶ Return  $\hat{\pi} \in \arg \max_{\pi \in \hat{\Pi}} U(\pi, D)$ .

## Regret of the finite hypothesis algorithm.

With probability  $1 - \delta$

$$U(\hat{\pi}, P) \geq U(\hat{\pi}^*, P) - \sqrt{2 \ln(2|\hat{\Pi}|/\delta)/T} \quad (3)$$

$$U(\pi^*, P) - U(\hat{\pi}, P) \leq \Delta + \sqrt{2 \ln(2|\hat{\Pi}|/\delta)/T} \quad (4)$$

## Examples

- ▶ ML estimation:  $U(\theta, D) = P_{\theta}(D)$  is the data likelihood.
- ▶ Accuracy, etc:  $U(\pi, D)$ .

# VC Dimension

Here we consider sets  $\Pi$  of deterministic rules  $\pi : X \rightarrow \{0, 1\}$ .

## Shattering

If a  $S \subset X$  can with  $|S| = m$ , can be assigned any labelling  $y_1, \dots, y_m$  by a  $\pi \in \Pi$ , then we say  $\Pi$  shatters  $S$ .

## The VC dimension

This is the largest-size set  $S$  that  $\Pi$  can shatter.

## Example: Perceptrons on $\mathbb{R}^2$

This class has VC dimension 3 on the plane.

# Binary classification

## Learning algorithm $\lambda$

- ▶ Takes data  $D = \{(x_t, y_t)\}$  as input
- ▶ Generates deterministic decision rules  $\pi : X \rightarrow \{0, 1\}$ ,

## The loss of a rule $\pi$ .

- ▶ Assume an existing concept class  $\pi^* \in \Pi$
- ▶ Distribution  $x_t \sim P$  is i.i.d. and  $x_1, \dots, x_T \sim P^T$ .
- ▶ The loss under distribution  $P$  is

$$L(\pi) = P(\{x : \pi(x) \neq \pi^*(x)\})$$

## Realisable PAC learner

- ▶  $\lambda : (X \times Y)^* \rightarrow \Pi$  is  $(\epsilon, \delta)$ -PAC, if for any  $P$  and  $\epsilon, \delta > 0$ , and any concept  $\pi^* \in \Pi$ , there is  $T$  such that

$$P^T(\{D : L[\lambda(D)] > \epsilon\}) < \delta, \quad D = (\{x_t, \pi^*(x_t)\}), x_t \sim P.$$
